Devices for performing these treatments typically have a hollow tube member having a smaller end portion for insertion into the patient, and a larger end portion for retaining a removable tip or a fluid-filled orifice. These devices typically include a series of flaps or wings which extend from the device in a circumferential direction away from the device, and which are folded inwardly to a closed position, and outwardly to an open position. The wings are designed to be folded in a closed position around the patient and retained in the open position, such as by the elastic force of a spring. When the device is inserted into a patient, the spring causes the wings to open outwardly. During the time the wings are open, the treatment may be performed. After the device is withdrawn from the patient, the wings are allowed to close, and the device may be retained within the patient, such as by magnetic means, gravity, and so on. In many prior art devices, the wings typically have a curved configuration. The wings are typically folded outwardly in a direction approximately perpendicular to the longitudinal axis of the device. The material and thickness of the wings is typically sufficient to adequately retain the wings in the open position while the device is inserted
